Abstract

Hydrogen sulfide (H₂S) is an endogenously synthesized gaseous molecule which along with nitric oxide and carbon monoxide induces a number of effects in cardiovascular system in normal and pathological conditions. In the present study the effects and underlying mechanisms of H₂S donor, sodium hydrosulfide (NaHS), on isometric force of frog myocardium contraction were studied. NaHS in the concentration of 100 μ M induced a negative inotropic effect and decreased the maximal velocity of contraction and relaxation of isolated ventricle strips. The substrate of H₂S synthesis L-cystein (200 μ M and 1 mM) induced the same effect and the inhibitors of cystathionin γ -lyase, H₂S-producing enzyme in heart, β -cyanoalanin (500 μ M) and propargylglycine (500 μ M) increased the amplitude of contraction. Inhibition of cystathionin γ -lyase by β -cyanoalanin prevented the negative inotropic effect of L-cystein. After inhibition of adenylate cyclase by MDL12,330A (3 μ M) or phosphodiesterases by IBMX (200 μ M) effect of NaHS was lesser than in control. In the presence of membrane-penetrating analogous of cAMP, 8Br-cAMP (100 μ M) and pCPT-cAMP (100 μ M), negative inotropic effect of NaHS completely retained. The effect of NaHS significantly decreased after preliminary application of the NO donor, SNAP (10 μ M), and did not change after inhibition of NO-synthases by LNAME (100 μ M). The obtained data suggest the possibility of endogenous synthesis of H₂S in frog myocardium and regulation of its contractility by activation of phosphodiesterases hydrolyzing cAMP, which leads to a decrease of activation of cAMP-dependent protein kinases and phosphorylation of voltage-dependent L-type Ca-channels. As the result, a reduction of calcium entry into cardiomyocytes decreases the contractility of frog myocardium.
